We would like to express our appreciation to our readers, Professor Timothy Roach and Professor Robert Garvey, for their time and valuable contributions to this thesis. We would also like to thank Professor Roach for his generosity in allowing us to work in his lab and for allowing us to use some pieces of his laboratory equipment. Without these contributions this thesis would not have been possible.

We also owe thanks to Professor Janine Shertzer for contributing to the editing of this thesis and to Professor De-Ping Yang for his invaluable assistance in the construction of our lock-in amplifier. We are very grateful for the help that we have received from Dick Miller, the college machinist, in constructing some of the parts for our laser. Also, we thank Diane Jepson, the Physics Department Administrative Assistant, for helping us with ordering the parts for our experiment.

We are especially grateful to the Richard B. Fisher Summer Student Research Fellowship Fund, the Research Corporation, the College Honors Program, the Summer Research Program, and the Physics Department for their generous support.
Abstract

We have designed, constructed, and tested a lock-in amplifier with readily available electronic components and homebuilt analog circuits. Its performance is comparable to that of a commercial unit, but it costs significantly less and is much more compact. The various components of our lock-in amplifier are discussed and the basic principles behind the function and operation of this versatile device are explained. We have also assembled a laser system and used the output signal of our lock-in amplifier in a negative feedback loop to stabilize the frequency of our laser to an atomic reference frequency.

Introduction

1.1 The Laser

The laser is an extremely useful device that is utilized in a wide variety of scientific, industrial, commercial, and medical applications. In a remarkably short report of only two pages, the first working laser was introduced by Theodore Maiman on 16 May 1960 at the Hughes Research Laboratory in California [1]. Since then, the laser has not only created a multi-billion dollar industry, but it has also revolutionized science and technology in countless and significant ways [2]. For instance, today the laser is being used to investigate the properties of atoms to an unprecedented level of precision. Lasers are integral components of the technology used in nano- and atomic-scale length metrology, optical communications, and precision spectroscopy, all cutting-edge areas of research in physics [3].

Dramatic new developments have been made and are still being made using lasers, such as their use in slowing down atoms to extraordinarily low temperatures that have never before been achieved. This new level of control of atomic motion is allowing researchers today to better observe and understand the behavior of atoms [4]. However, such applications are only possible with a laser which emits light with a single, exceptionally stable frequency. In this thesis, we show how this precise level of frequency stability can be attained using a lock-in amplifier and a fixed reference frequency against which the laser frequency can be stabilized.
1.2 Our Lock-In Amplifier

A lock-in amplifier is a very sensitive electronic device used to detect, isolate, and amplify very small AC signals that may be buried in substantial amounts of unwanted noise. The lock-in amplifier is extremely versatile and is used in many fields of physics, including atomic physics. For instance, in solid-states physics, it is used to measure the temperature dependence of the resistance of metals and superconductors, study the Hall Effect in semiconductors, and detect small temperature changes by means of a thermistor bridge [5]. The lock-in technique is also used in some astrophysical experiments involving the measurement of cosmic radiation [6].

In this thesis, we describe the construction of a lock-in amplifier using readily available electronic components. Our lock-in amplifier consists of five different types of circuits, which we have designed and built. They include the following: a differential AC amplifier, a phase shifter, a mixer, a low-pass filter, and a DC amplifier. These circuit components have been tested both individually and collectively, and they have met our design goals. In our experiment, our lock-in amplifier is used to detect a laser frequency change and produce a signal voltage which can be fed back to our laser to correct this change, thereby stabilizing the laser frequency.

1.3 Our Laser Setup

In our experiment, we wish to stabilize the frequency of a diode laser. In comparison to many other laser sources, the output power of a diode laser is very stable, allowing for easier measurements of absorption or fluorescence [7]. These lasers are also inexpensive, very compact, and available in many wavelengths which can be tuned over a few nanometers.

Diode lasers emit light over a narrow range of frequencies. However, the laser frequency varies with small fluctuations in the laser current and temperature. These fluctuations
are undesirable in precision experiments. By stabilizing the laser frequency to a stable external optical reference, it is possible to narrow the range of wavelengths that are emitted by the laser over time [8]. For a reference frequency, we use a specific atomic transition. The frequency of light needed to excite such a transition is fixed by the atomic properties of the reference gas and is therefore very stable.

A diffraction grating is included in our laser setup to allow us to control the frequency of our laser. The grating allows for passive stabilization as well as external control. When the output beam of the laser strikes the grating, the first-order diffracted beam is directed back into the laser, providing frequency-selective optical feedback [9]. This feedback keeps the laser producing light at the same frequency as that of the optical feedback. Different lasing frequencies may therefore be selected by adjusting the grating angle. This control allows us to keep the laser frequency the same as the frequency of the external reference.

1.4 Stabilizing the Frequency of Our Laser

We wish to generate a control signal, commonly called an error signal, that we can use to stabilize the frequency of our laser. In order to do this, we impose a dither (a small modulation) on the laser frequency by repeatedly changing the grating angle back and forth at $\omega_d$. An absorption signal is acquired by measuring the laser light passing through the atomic reference gas with transition frequency $\omega_0$. The absorption signal is fed into our lock-in amplifier, which provides an output signal that is directly proportional to the amount of $1\omega_d$ (dither frequency) signal present in the absorption signal, while ignoring all other frequency components. The output signal of our lock-in amplifier serves as an error signal that is proportional to the first derivative of the absorption signal. Therefore, when the laser frequency $\omega_{\text{laser}}$ exactly matches
the external reference frequency $\omega_o$, no error signal is generated [10]. However, a drift towards higher or lower laser frequency results in an error signal that is directly proportional to the amount of frequency drift. The error signal therefore provides a continuous restoring signal that can be used to keep the laser frequency locked to the atomic reference frequency. Fig. 1.1 displays the absorption signal and the amplitude of the dither signal at different laser frequencies. Fig. 1.2 shows the error signal that is derived from the absorption signal by our lock-in amplifier at different laser frequencies.

**Fig. 1.1:** This is an example of an absorption signal obtained from an atomic reference. When the laser frequency differs from the reference frequency, a $1\omega_d$ signal is present. The amplitude of this signal, measured by our lock-in amplifier, depends on the magnitude of the frequency difference. On the other hand, when the laser frequency equals the reference frequency, no $1\omega_d$ signal is present.
Fig. 1.2: This is the error signal used for locking at the reference frequency, $\omega_o$. It is the first derivative of the absorption signal in Fig. 1.1. The error signal is described in more detail in Chapter 5.

1.5 Project Overview

In this paper, we discuss how the signal from our lock-in amplifier can be fed back to a diode laser, which we have assembled, in order to stabilize its frequency to an atomic reference frequency. This first chapter has served as an introduction. The rest of this paper is organized as follows. In Chapter 2, we describe the design, construction, operation, and testing of our lock-in amplifier. Chapter 3 describes our laser setup and frequency tuning parameters. In Chapter 4, we review saturated absorption spectroscopy and our optical setup. In Chapter 5, we discuss frequency stabilization of our laser to an external reference frequency. Fig. 1.3 displays graphically how the different parts of our overall setup fit together.
Fig. 1.3: This is our overall setup for stabilizing the frequency of our diode laser using our lock-in amplifier. The laser frequency is dithered over the atomic reference frequency to generate the absorption and error signals.
Chapter 2

Our Lock-In Amplifier

2.1 Introduction

The lock-in amplifier is an extremely useful device with applications in many scientific disciplines. For instance, in spectroscopy and studies of fluorescence and luminescence, it is used to recover very small optical signals. In electronics and cryogenics, the lock-in amplifier can be used in component characterization, bridge networks, and measurements of the resistance of superconductors. This versatile device can also be used as an AC signal recovery instrument, a vector voltmeter, a phase meter, a spectrum analyzer, and a noise measurement unit. Evidently, the lock-in amplifier is an invaluable addition to any physics laboratory.

As noted in Chapter 1, the purpose of our lock-in amplifier is to provide a DC output voltage, the “error signal,” proportional to the amount of $1_{\omega d}$ signal present in the lock-in input signal. In this chapter we describe how this is accomplished with our lock-in amplifier.

Our lock-in amplifier is based on a design by M. Weel and A. Kumarakrishnan [10]. It is composed of five major parts: a differential AC amplifier, a phase shifter, a mixer, a low-pass filter, and a DC amplifier. Fig. 2.1 displays the overall setup of our lock-in amplifier, which is discussed in this chapter.
Fig. 2.1: This is a schematic showing the major parts of our lock-in amplifier. Provided with both a dither signal of frequency $\omega_d$ and an input signal, our lock-in amplifier produces an error signal proportional to the amount of $\omega_d$ signal present in the input signal.

2.2 Dither and Input Signals

Our lock-in amplifier requires a dither signal and an input signal. The dither signal defines the frequency, $\omega_d$, at which our lock-in amplifier recovers signals from the input channel. In general, the dither signal stimulates an experiment, and the experiment responds at the same frequency. This response is the input signal for the lock-in amplifier. In our experiment, the dither signal is provided by an external sine-wave generator. The input signal comes from the Doppler-free saturated absorption spectrum of the Rubidium atom (Chapter 3).

2.3 Differential AC Amplifier

The input signal is filtered and amplified to a level that is suitable for the mixing stage. This is achieved by means of a high-pass filter coupled with a differential AC amplifier. Fig. 2.2 displays the particular circuit that we have constructed and use.
**Fig. 2.2:** The input signal is filtered by a high-pass filter. A differential AC amplifier amplifies the filtered signal by a factor of 50. This amplification is shown in Fig. 2.3.

The high-pass filter in Fig. 2.2 blocks any DC offset voltage that the input signal might have. The filter has a very low cutoff frequency, $f_{3dB}$ (discussed in Section 2.6), of 160mHz to avoid reducing the amplitude of the AC signal. The $\omega_d$ value that we use in our experiment is 512Hz, which is well above the cutoff frequency.

The filtered input signal is fed into the differential AC amplifier. The output of this circuit is proportional to the difference between the filtered input signal and ground. The differential AC amplifier cancels out any signal that is present in both (e.g., noise), and it amplifies any signal that is different (e.g., our desired signal).

We tested our circuit by feeding a small amount (4%) of the dither signal, provided by a sine-wave generator, into the input channel. Fig. 2.3 demonstrates the amplification of the input signal by the differential AC amplifier circuit.
Fig. 2.3: A portion (4%) of the dither signal is used as a test input signal. Since it does not stimulate an experiment, no “noise” is present. This figure shows the amplification of the test input signal by a factor of 50. This is achieved by our differential AC amplifier circuit.

The gain of our AC differential amplifier is not restricted to be 50. The resistor, R_G, in Fig. 2.2 may be varied resulting in gains up to a factor of 1000. Different gains can be chosen depending on the size of the input signal. A typical desired voltage level out of the AC amplifier is 2V.

2.4 Phase Shifter

The dither signal typically has a phase shift with respect to the input signal arising from the response of the laser system and the optical system (see Fig. 1.3). Having control over the relative phase difference between the dither and input signals is crucial in the generation of the final output signal of the lock-in amplifier. We have constructed a phase shifter (Fig. 2.4) that makes it possible to change the phase of the dither signal.
Fig. 2.4: The phase shifting circuit includes a variable resistor (R = 0 to 5kΩ) which makes it possible to shift the phase of the dither signal.

As displayed in Fig. 2.4, the phase shifting circuit consists of a 5kΩ potentiometer (variable resistor), which allows us to change the resistance and therefore the phase of the dither signal. Fig. 2.5 demonstrates the dependence of phase shift on resistance, R.

Fig. 2.5: The phase shift is greater at lower resistance values. As the resistance is increased, the phase shift becomes smaller. When the resistance is 0Ω, the dither signal is phase shifted 180°. When the resistance is increased to 5kΩ, the dither signal is phase shifted about 5°.
The phase shifting circuit makes it possible to shift the phase of the dither signal up to 180°. Also, the phase shifter does not change the amplitude of the dither signal. Two phase shifters are included in our lock-in amplifier to provide nearly a full 360° shifting range. Although our two phase shifters shift from 10° to 360°, rather than the full 0° to 360°, the range is sufficient. Figs. 2.6 a) and b) show the effect of the phase shifting circuit in aligning the phase of the dither signal with that of the input signal.

**Fig. 2.6 a):** The dither and input signals are typically out of phase. We can correct this misalignment by means of our phase shifter (see Fig. 2.6 b).
Fig. 2.6 b): By means of the phase shifter, the dither and input signals have been made in phase with respect to one another. The alignment of these signals is important in the mixing stage. Under the in-phase condition, the mixer output signal is maximized. Figs. 2.8 a) and b) demonstrate the importance of the alignment of the dither and input signals in producing the maximum DC voltage.
2.5 Mixer

At the heart of our lock-in amplifier is a frequency mixer which multiplies the amplified input signal with the phase-shifted dither signal. Fig. 2.7 displays the mixer circuit.

**Fig. 2.7:** The filtered and amplified input signal is fed into one of the inputs of the mixer. The dither signal, phase shifted so that it is in phase with the input signal, is also provided. Fig. 2.6 b) displays both signals. The mixer combines these signals to produce a mixed signal containing the sum and difference frequencies. For our experiment, \( \omega = \omega_d \). The mixer output signal therefore has a DC voltage resulting from the difference component, as well as an AC voltage at \( 2\omega_d \) (twice the dither frequency) resulting from the sum component. The mixer we use (AD633AN) also reduces the signal by a factor of 10 (not displayed).

When two waveforms, \( V_{in}(t) \) and \( V_d(t) \) in Fig. 2.7, are multiplied together, the result \( V_{mixed}(t) \) contains the sum and difference frequencies, \((\omega + \omega_d)\) and \((\omega - \omega_d)\). In our case, since the input signal and the dither signal are at the same frequency \( (\omega = \omega_d) \), the difference frequency is zero and the result is a DC output which is proportional to the amplitude of the input signal, \( A \). As previously discussed, the phase difference between the input signal and the dither signal can be brought to zero by the phase shifters. The DC voltage is at its maximum value when the input and dither signals are in phase and equals \( \frac{AB}{2} \). Figs. 2.8 a) and b) show that the DC level is larger when the dither and input signals are in phase (2.8 b), rather than when out of phase (2.8 a).
**Fig. 2.8 a):** This is the mixer output when the dither and input signals are out of phase (Fig. 2.6 a). Both DC and $2\omega_d$ AC components of the mixer output are clear. The difference frequency is a DC voltage since the input signal is at the same frequency as the dither signal. In our case, $\omega_d = 500$Hz. The sum component yields an AC voltage at 1000Hz, or $2\omega_d$, as expected.

![Mixer Output (dither and input signals 60° out of phase)](image)

$V_{d.c} = 11$mV

**Fig. 2.8 b):** When the dither and input signals are in phase (see Fig. 2.6 b), the DC output voltage is at a maximum. This can be achieved by the phase shifter.

![Mixer Output (dither and input signals in phase)](image)

$V_{d.c} = 24$mV
As indicated in Figs. 2.8 a) and b), in addition to the DC component another component at twice the frequency of the dither signal \(2\omega_d\) results from the mixing. This is the sum frequency. This component is eliminated so that the output of our lock-in amplifier is only the DC voltage.

### 2.6 Low-Pass Filter

The output from the mixer (Fig. 2.8 b) goes through a low-pass filter to remove the \(2\omega_d\) component. The low-pass filter circuit that we have constructed and use is shown in Fig. 2.9.

![Fig. 2.9: A low-pass filter is used to eliminate the \(2\omega_d\) component in the mixer output. It has a cutoff frequency of 2Hz (which may be varied) so as to avoid attenuating the DC voltage. Fig. 2.10 shows how the low-pass filter operates.](image)

In general, a low-pass filter operates similar to a high-pass filter (Section 2.3). However, it reduces the amplitude of signals with frequencies higher than the cutoff frequency, \(f_{3dB}\), at which 70% of the original signal voltage (half the initial power) is allowed through.

\[
f_{3dB} = \frac{1}{2\pi RC} = \frac{1}{2\pi \tau}
\]  

[Eq. 2.1]

Where \(\tau = RC\) is the time constant. In our circuit, we can vary the \(f_{3dB}\) of the low-pass filter by changing \(R\) \((\tau = 1\text{ms to 3s} \rightarrow f_{3dB} = 50\text{mHz to 160Hz})\). In addition to the \(2\omega_d\) signal, the mixer output also inevitably contains some noise components at many different frequencies. The
majority of the noise components are also attenuated by the low-pass filter. By increasing the
time constant, the noise components can be reduced further. However, in the process, the cutoff
frequency is lowered and we risk attenuating the desired DC voltage which in a real experiment
slowly varies with time. We therefore have a trade-off. Fig. 2.10 displays the effect of a low-pass
filter in attenuating higher frequency components.

Fig. 2.10: This figure shows the attenuation of a signal by a low-pass filter.
Frequencies below $f_{3dB}$ are allowed through without much attenuation. Signals
with higher frequencies are greatly reduced. At $f_{3dB}$, 70% of the original signal is
allowed through. Notice that for this data the low-pass filter is set to $\tau = 5$ms. This
does not reflect the low-pass displayed in Fig. 2.9 which is set to $\tau = 100$ms.

At the output of the low-pass filter, we have the DC error signal that we desire. Fig. 2.11 shows
the effect of the low-pass filter in eliminating the higher frequency component, the $2\omega_d$ voltage,
of the mixer output (Fig. 2.8 b), leaving only the DC component, which we call the error signal.
Fig. 2.11: This is the signal produced by our lock-in amplifier after the low-pass has filtered out the $2\omega_d$ component of the mixer output signal (Fig. 2.8 b). It is essentially the frequency difference component, or the DC voltage, of the mixer output. This is our desired error signal before the final DC amplifier.

### 2.7 DC Amplifier

A variable DC amplifier (gain = 1 to 500) after the low-pass filter amplifies the error signal to a suitable level for the experiment at hand. The circuit, identical to that of the AC amplifier but without a high-pass filter and not differential (no AC coupling), is shown in Fig. 2.12.

Fig. 2.12: This is the DC amplifier circuit used to amplify the error signal by a factor of 10. This amplification is shown in Fig. 2.13. Since the error signal is fed into the inverting (-) input of the AD620 op amp, the amplified output error signal is inverted with respect to the unamplified input error signal (see Fig. 2.11).
Fig. 2.13 displays the final output error signal of the lock-in amplifier that is crucial in our experiment. The signal is inverted by the DC amplifier.

**Fig. 2.13:** The DC amplifier inverts the error signal and amplifies it by a factor of 10. This is the final output of our lock-in amplifier!

The total gain of the error signal at the output of the lock-in amplifier is the product of both the AC and DC amp gains as well as the mixer “gain” (which is not quite a true gain, but it does change the amplitude). In our case, since the gain of the AC amplifier is set to 50 (see Fig. 2.2) and that of the DC amplifier is set to 10 (see Fig. 2.12), the total gain is 50 after taking the gain of the mixer (1/10) into consideration. Dividing the gain between these amplifiers affects the stability of the error signal. The output of our lock-in amplifier is most stable when most of the gain is in the AC amplifier because it is less sensitive to slow drifts.
In Chapter 5, we further discuss the error signal and explain how we use it to stabilize the frequency of a diode laser (Chapter 3) to a transition in the Rubidium atom by means of Doppler-free saturated absorption spectroscopy (Chapter 4).

Fig. 2.14: This is our final lock-in amplifier circuit. For details regarding the particular components that we use and their purpose, simply refer to the section of interest in this chapter.
**Fig. 2.15:** This is the inside of our lock-in amplifier. The top knobs change the resistance and therefore the gain of the AC and DC amplifiers. The DC amplifier has a gain range from 1 to 500. Since it is less sensitive to slow drifts, the AC amplifier has a greater gain range from 1 to 1000. Also, taking into consideration the “gain” of the mixer, the maximum gain of our lock-in amplifier is 50,000. The bottom knob allows us to change the time constant of the low-pass filter by selecting a different resistor. The available time constant settings are 1ms, 10ms, 30ms, 100ms, 300ms, 1s, and 3s. The dither and the input signals enter from the left, go through their respective circuits and are mixed. The error signal channel is on the right. Two potentiometers (blue boxes above the phase shifter op amps) are used to change the resistance and therefore phase shift the dither signal.
**Fig. 2.16:** This image is included as a size comparison. The dimensions of our box are 6x4x2 inches. Two holes have been drilled through the top of the box to allow for a screwdriver to fit through in order to change the resistance of the phase shifter potentiometers. The graphs on the box reveal tell us the resistance as a function of the number of turns. The knobs are for the AC and DC gain. Our lock-in amplifier requires a ±12V power supply. The input and dither signal channels are also displayed. We also include the option of grounding the input signal to the box.
Chapter 3

Our Laser Setup and Frequency Tuning Parameters

3.1 Introduction

A laser diode emits a narrow range of frequencies. However, drifts in frequency occur over time due, for example, to changes in laser temperature and current, as well as mechanical vibrations in the apparatus. These frequency drifts make the laser unsuitable for experiments that require high frequency stability. We want to make our laser operate at a specific frequency and keep it lasing at that frequency for a long period of time (several hours) with very little or no drift.

There exist three important ways of adjusting the frequency of our laser. These are the laser temperature, the electrical current (injection current) provided to the laser diode, and optical feedback from a diffraction grating. By adjusting these parameters, the output frequency of our laser diode can be tuned.

In this chapter, we describe the laser system that we assembled. Our laser setup consists of five main parts: the laser diode, our mechanical setup, temperature control, injection current control, and grating optical feedback control. The apparatus is shown in Fig. 3.1.
Fig. 3.1: This is our laser setup which took time and effort to build. The laser diode is maintained inside a collimation tube which is mounted securely on a commercial laser mount. A moveable commercial mount, holding a diffraction grating and a mirror, is attached to the laser mount. A PZT (see Section 3.6), sandwiched between the mounts, is used to move the moveable mount and, therefore, change the angle at which the laser light hits the grating. Light is sent back into the laser by the grating. The grating also reflects light to the mirror (not visible) and out to the experiment. We refer to this figure throughout this chapter.

3.2 The Laser Diode

A laser diode is a semiconductor chip that converts an applied electrical current into light. In our experiment, we use an infrared laser diode which lases at 780nm and yields an output power of 20mW at an injection current of 65mA. Our aim is to stabilize the frequency of the light that is produced by this laser.
The injection current, necessary to run our laser, is provided by a commercial low noise current driver. As displayed in Fig. 3.2, there is a sudden increase in the laser power output after a threshold current (≈25mA) has been reached. This is the injection current at which our laser begins to lase. Above the threshold, the power output of our laser is approximately linearly dependent on the injection current. We used a power meter to acquire the data in Fig. 3.2.

![Power versus Injection Current](image)

**Fig. 3.2:** Our laser begins to lase after the threshold current has been reached.

The light emitted by our laser is highly divergent. We collimate the light so that, throughout our experiment, the diameter of the laser beam does not change significantly. A constant beam size is useful when we perform saturated absorption spectroscopy (Chapter 4). The laser diode is securely mounted inside a collimating tube consisting of an aspheric lens through which the light passes. We manually collimate the light by translating this lens closer to or farther away from the laser diode until it is at a distance equal to the focal length of the lens. At this point, the laser light is collimated. The collimating tube, containing the lens and the laser diode, is mounted on a commercial laser mount that is fixed.
3.3 Our Mechanical Setup

A thermoelectric cooler (TEC) maintains the laser diode at a set temperature by actively cooling or heating the entire mechanical setup. In order to ensure that the entire laser setup is at the same temperature, all parts have been polished to ensure maximum surface contact between adjacent surfaces. We also use heat-conducting thermal paste to optimize thermal conductivity.

The TEC is driven by a commercial temperature controller which stabilizes the temperature of the laser to the set temperature within approximately 0.005°C. The TEC is sandwiched between two conductive aluminum plates at the base of the laser mount and is coupled to a thermistor: a resistor whose resistance varies with temperature. The thermistor, buried inside the laser mount (not visible in Fig. 3.1), serves as a laser temperature sensor for the controller.

The entire laser setup is mounted on an aluminum block which serves as a large heat sink. The block is mounted stably on the optical table which provides vibrational and mechanical stability and dampening. Our laser is covered with an aluminum box which blocks out any unwanted light and air currents which interfere with the laser. The box has an opening just large enough to allow the laser beam out. Lastly, to further block out any air currents and moisture, our laser is also encased in a larger plexiglass box covered with material that absorbs sound waves and keep out any light from the environment. The hole in this box is also just large enough to let the laser light out.
3.4 First Tuning Parameter: Laser Temperature

Thermal expansion changes the cavity length of the semiconductor chip in the laser diode. An increase in temperature increases the cavity length and increases the resonant wavelength. It also shifts the semiconductor gain peak toward longer wavelengths (shorter frequencies). The laser frequency can be changed by changing the temperature of the laser.

The temperature of the laser diode may be adjusted externally. We can vary the temperature from 15 to 40°C, and a typical temperature tuning is 0.03 nm/°C, or 15GHz/°C. The advantage of using this tuning parameter is that large changes in frequency are possible. However, there are disadvantages. First of all, it can take up to half an hour for the temperature of the laser to stabilize completely. Also, with this tuning parameter it is very difficult to make small changes in laser frequency, and so the tuning that can be achieved is very coarse.

3.5 Second Tuning Parameter: Injection Current

Unlike direct temperature control, the injection current raises the laser temperature internally by means of joule heating. Increased electron density also changes the refractive index. As a result, the response from laser current tuning is faster than from external heating. We measured the variation of laser frequency with injection current as shown in Fig. 3.3. There is a linear dependence of laser frequency on current. For every mA change in the injection current, the laser frequency changes by 2.4GHz. We use this tuning parameter extensively to tune the frequency of our laser.
Fig. 3.3: This figure displays frequency versus injection current for our laser. We use the injection current to tune the frequency of our laser to the required value. This tuning parameter elicits a faster laser response than the TEC. It allows for very fine adjustment in the laser frequency. For every mA, the frequency can be changed by 2.4 GHz. Large changes in frequency are not possible with this tuning parameter. We can only make changes up to 5GHz at best.

3.6 Third Tuning Parameter: Grating Optical Feedback

As displayed in Fig. 3.1, light emitted by the laser diode strikes a grating. The grating reflects a narrow frequency range back into the laser, forcing the laser to emit light within that particular frequency range. By changing the angle of the grating with respect to the incoming light, different frequencies may be sent back into the laser, making it possible to tune the laser to a particular frequency range.

The grating is mounted on a custom made aluminum piece which is attached to the modified “moveable commercial mount” displayed in Fig. 3.1. The moveable commercial mount is attached to the fixed laser mount, but it can be moved. Adjustable screws are used to coarsely
adjust the grating angle by pushing on the modified mount. Finer adjustment is achieved by a piezoelectric transducer (PZT) which is sandwiched between the laser mount and the modified mount holding the grating. The PZT stack, made of ceramic material, either expands or contracts in response to an applied DC voltage, provided by a PZT driver, which can be as high as 150V. The expansion of the PZT is proportional to the applied voltage. Fig. 3.4 displays the influence of PZT voltage on the frequency output of the laser.

![Frequency versus PZT Voltage](image)

**Fig. 3.4:** Voltage applied to the PZT changes its thickness, thereby causing the modified mount to move, changing the angle of the grating relative to the laser light. When the grating angle is changed, a different frequency range is fed back into the laser, causing the laser to lase within that frequency range. As with laser current, this tuning parameter allows for fine frequency adjustment. For every volt that is applied to the PZT by the PZT driver, the frequency of the laser can be changed by 190MHz. This tuning parameter also elicits a faster laser response than the TEC.
3.7 Closing Remarks

The tuning parameters presented in this chapter make it possible to control the frequency output of our laser. At the level of precision that we need for our experiment, however, the laser is not adequately stabilized by simply adjusting these parameters and holding them constant. Therefore, we need a way of continuously adjusting these parameters so that the laser frequency does not deviate from a stable reference frequency. We discuss in Chapter 5 how the signal from our lock-in amplifier can be used in a negative feedback loop to stabilize the frequency of our laser. However, we must first establish a reference frequency. This is covered in Chapter 4.
Chapter 4

Our Optical Setup and Saturated Absorption Spectroscopy

4.1 Introduction

In order to stabilize the frequency of our laser, we need a highly stable optical reference frequency. The hyperfine atomic transitions of the Rubidium-85 isotope provide the level of stability that we need. We use a technique known as Doppler-free saturated absorption spectroscopy to produce a spectrum of narrow peaks to which we can lock the frequency of our laser by means of feedback from our lock-in amplifier. These peaks correspond to different hyperfine transitions of $^{85}\text{Rb}$. By carefully adjusting the laser temperature, injection current, and grating angle, as described in Chapter 3, our laser can be tuned to one of these hyperfine atomic transitions.

Our optical setup is divided into two main parts: a laser frequency monitoring section and the Doppler-free saturated absorption apparatus. Fig. 4.1 displays our overall setup.
**Fig. 4.1:** This is our optical setup. A portion of the laser light is directed towards a Fabry-Pérot spectrum analyzer and a wavemeter which allows us to monitor the output frequency of the laser. The laser beam is split into three beams by a beam splitter (BS3). Two of these beams (the probe beams) arise from the reflection off the front and back surfaces of a beam splitter. They are identical in intensity and pass through a vapor cell of Rubidium atoms. Each probe beam is then detected by a photodiode. The transmitted beam from BS3 (the pump beam) is more intense than the probe beams. By means of two mirrors, the pump beam is directed through the vapor cell from the other end and is made to overlap with one of the probe beams.
4.2 Monitoring the Laser Frequency

Before entering the setup for saturation absorption spectroscopy, a small portion of the laser light is immediately deflected aside by BS1 for monitoring purposes. In order to tune the laser frequency to the precise level of an atomic reference frequency, it is important to constantly know the characteristics of the laser light.

A Fabry-Pérot spectrum analyzer makes it possible to determine if the laser is emitting a single or multiple wavelengths of light. This device is made up of two mirrors facing one another that are spaced in such a way that only light with a certain wavelength resonates in the space (the cavity) between the mirrors. One of these mirrors is fixed, while the other is moved (or scanned) back and forth, changing the cavity length. Typically, at two points in the scan, resonance is achieved. A photodiode behind the mirror cavity monitors the resonant transmission and displays it on an oscilloscope. Fig. 4.2 shows a typical Fabry-Pérot signal. In this case, the laser is emitting a single wavelength of light. The appearance of any side peaks in the signal would indicate that the laser is operating at multiple wavelengths.

In Chapter 3, the Fabry-Pérot spectrum analyzer was used to determine how the laser frequency changes with laser current (Fig. 3.3) and PZT voltage (Fig. 3.4). This device has proven to be indispensable when tuning the laser frequency to the atomic reference frequency.

In addition to the Fabry-Pérot spectrum analyzer, a wavemeter is used to determine the absolute operating wavelength of the laser. The wavemeter is able to perform this function by comparing the wavelength of the laser beam to that of an internal reference laser. This device is also very useful when tuning the frequency of our laser. We use it to confirm that the frequency of our laser is close to the atomic reference frequency.
Fig. 4.2: The Fabry-Pérot spectrum analyzer, composed of two mirrors and a photodiode, allows us to ensure that the laser is operating at a single wavelength of light. One mirror is fixed and the other one is moved back and forth. As described in the text, two signals are detected, and for our particular Fabry-Pérot cavity these two peaks are 1500MHz apart.

Backscattered light from any of the components in our optical setup could very easily destabilize the frequency of our laser. Unwanted optical feedback adds frequencies that would compete with the frequency being fed back to the laser by the grating. In order to deal with this problem, an isolator is included in our setup. This optical element helps to prevent unwanted optical feedback by allowing the transmission of the laser light in only one direction. We also keep track of harmful reflections and slightly misalign, on purpose, some of our optical elements, such as the Fabry-Pérot spectrum analyzer, so that the light it reflects is directed to a point where it cannot get into our laser. Apertures are also used, where necessary and where they do not cause backscattering, to block unwanted beams.
4.3 Rubidium Vapor Cell

Our saturation absorption spectroscopy setup includes a vapor cell of Rubidium atoms maintained at room temperature. The atomic transition of $^{85}\text{Rb}$, occurring at a very specific wavelength of 780.245nm, provides a highly stable reference frequency for locking our laser. When the laser is tuned precisely to the atomic transition frequency, absorption of the laser light by atoms in the 5s ground state takes place (see Fig. 4.3). These atoms become excited as their electrons are promoted to the 5p excited state. When these excited atoms eventually decay back into the ground state, fluorescence occurs as the absorbed light is re-emitted in all directions.

Along with the wavemeter, we can use an observation of fluorescence to confirm that the laser is at the correct frequency to excite $^{85}\text{Rb}$. The atomic transition of $^{85}\text{Rb}$, in fact, branches off into three hyperfine atomic transitions each of which occurs at a unique frequency. These transitions are the $F=3$ to $F’=2$, 3, or 4 transitions displayed in Fig. 4.3.

Since the Rubidium atoms in the cell are in a gaseous phase, they are in constant motion because of their thermal energy. These atoms are characterized by different velocity classes according to the magnitude of their speed and direction of motion. The zero velocity class, in particular, refers to those atoms that are not moving.
Fig. 4.3: This is the $^{85}$Rb level diagram. Transitions from a ground state to an excited state must follow quantum mechanical selection rules. In the case of the transitions from the $F=3$ ground state energy level for $^{85}$Rb to the four $F'$ excited state energy levels, there can only be three possible transitions, as illustrated.

4.4 Doppler-Broadened Absorption Spectrum

When the laser frequency is on resonance with the atomic transition frequency of $^{85}$Rb, some of the laser light is absorbed by the atoms. As a result, the photodiodes detect less light from the probe beams. By scanning the frequency of our laser back and forth across the atomic transition frequency of $^{85}$Rb, we produce an absorption spectrum (see Fig. 1.1). Intuitively, this spectrum should consist of narrow dips which correspond to the hyperfine transition frequencies of $^{85}$Rb. However, these dips are broadened due to a phenomenon called Doppler-broadening.
Doppler-broadening results from the motion of the atoms with respect to the direction of the laser beam. If an atom is traveling towards the beam, the laser frequency seen by the atom is greater than if it were stationary. As a result, if the laser frequency is slightly lower than that of the atomic transition frequency of $^{85}$Rb, the Doppler effect would make it seem as if it were on resonance with the transition. This corresponds to the lower frequencies of the Doppler-broadened absorption spectrum. A similar effect is observed in the case in which an atom is traveling away from the light beam. The apparent frequency is lower. As a result, light of slightly higher frequency is absorbed. This corresponds to the higher frequencies of the Doppler-broadened absorption spectrum. The zero velocity class of atoms does not contribute to Doppler broadening. These atoms, in fact, correspond to the summit of the absorption peak and, therefore, a transition frequency.

In order to acquire the absorption spectrum, the laser frequency is scanned by applying a ramp signal (0.1Hz, 0.5V) to the PZT driver, continuously expanding and contracting the PZT and changing the grating angle so that different frequency ranges are sent back into the laser one at a time. The ramp signal is provided by an external function generator. Fig. 4.4 displays the Doppler-broadened absorption spectrum that we obtained by scanning across the atomic reference frequency. Part of the ramp signal is also displayed.
Fig. 4.4: This is a portion of the Doppler-broadened saturated absorption spectrum obtained by scanning the laser frequency across the atomic transition of $^{85}\text{Rb}$. We observe a dip instead of a peak (as in Fig 1.1) because absorption of light results in a decrease in light to the photodiodes. The theoretical Doppler-broadened absorption spectrum has a full width half maximum of about 500MHz. Limited by our scanning range, we were only able to observe a portion of the dip.

4.5 Probe and Pump Beams

As displayed in Fig. 4.1, the main laser beam is split into three less intense beams: two probe beams and a pump beam. All three beams go through the Rubidium cell and are at the same frequency, but differ in intensity and direction of travel.

Two weak probe beams of approximately equal intensity (7% of the main beam intensity) are formed by the reflection of the laser beam off the front and back surfaces of BS3. As these identical beams pass through the $^{85}\text{Rb}$ vapor cell, they interact with the same velocity class of atoms. After the cell, each is detected by a photodiode which is sensitive to the infrared light.
Since it is transmitted through BS-3, the pump beam is much more intense (93% of the main beam intensity) than the probe beams. By means of two carefully-placed adjustable mirrors, the pump beam enters the Rubidium cell from the opposite end and is overlapped with one of the probe beams. Since the pump beam is at the same frequency as the probe beams, it interacts with a similar velocity class of atoms, but which travel in the opposite direction.

When the laser frequency is not on resonance with the atomic transition frequency of \(^{85}\text{Rb}\), the pump and the probe beams interact with different atoms traveling at the same speed, but in opposite directions. On the other hand, when the pump and the probe beams are on resonance with the atomic transition, they excite the same zero velocity class of atoms, which correspond to the transitions. When this happens, the pump and the probe beams compete for atoms to excite. Since the pump beam is much more intense than the probe beams, it has a greater probability of exciting these atoms. The pump beam significantly “saturates” the transition, reducing (by up to 50%) the number of atoms in the ground state available to the probe beam to excite. This phenomenon between the pump and the probe beams forms the basis of a technique for determining the hyperfine atomic transition frequencies of an atom. This technique is called saturated absorption spectroscopy.

4.6 Saturated Absorption Spectroscopy

The reduction by the pump beam of the number of atoms in the ground state when the laser is on resonance results in a reduction of the absorption of probe beam 1. More light is therefore detected by the photodiode and peaks form in the Doppler-broadened absorption spectrum (see Fig. 4.5). These narrow features correspond to each of the hyperfine atomic transitions of \(^{85}\text{Rb}\), as indicated in the figure.
Additional peaks (labeled “X” in Fig. 2.5), called “crossovers,” occur when the frequency of our laser falls exactly halfway between a pair of atomic transition frequencies. Both the pump and the probe beams excite atoms from the ground state, but to different excited states at the same time. In this case, the pump and the probe beams interact with the same nonzero velocity class of atoms. As a result, as in the case of the zero velocity class of atoms, there is a reduction in the absorption of the probe beam and consequently a detected absorption peak.

![Saturated Absorption Signal](chart.png)

**Fig. 4.5:** This is the saturated absorption spectrum formed when the frequency of our laser is scanned across the atomic transitions. The saturated absorption spectrum consists of a sequence of peaks superimposed on the Doppler-broadened spectrum. These peaks occur when the pump and probe beam 1 are resonant with each of the three hyperfine atomic transitions of $^{85}$Rb. Crossovers occurs when the laser frequency is halfway between two transitions. Since three hyperfine atomic transitions are possible, there exist three crossovers between: $F' = 2 \rightarrow 3$, $3 \rightarrow 4$, and $2 \rightarrow 4$. We maximize the amplitude of all of these peaks by having the pump beam and probe beam 1 overlap as much as possible (forming an angle of about 1°).
Probe beam 2, unaffected by the pump beam, reports the Doppler-broadened absorption spectrum (Fig. 4.4). The Doppler background is eliminated by subtracting the signals from probe beams 1 and 2 (see Fig. 4.6). The resulting Doppler-free saturated absorption signal consists of spectral peaks that correspond to regions of decreased absorption, or increased light to PD1.

**Fig. 4.6:** This is the Doppler-free saturated absorption spectrum obtained by taking the difference between the signals (Fig. 4.5) from probe beams 1 and 2.

### 4.7 Improving the Saturated Absorption Signal

For the hyperfine atomic transitions of $^{85}\text{Rb}$, the intensity required for saturation, $I_s$, is 1.6mW/cm$^2$. After the optical isolator, we include a 20dB neutral density filter (NDF) which transmits 1% of the laser light. Without affecting the laser frequency, the NDF attenuates the light, providing a suitable pump beam intensity ($2.7\text{mW/cm}^2 \approx I_s$) and probe beam intensity ($0.6\text{mW/cm}^2 < I_s$) for observing the saturated absorption spectrum with well-defined peaks. Fig. 4.7 shows the effects of varying the pump and probe beam intensities by using different NDFs.
Fig. 4.7: By reducing the intensity of the laser output, we are able to get well-defined peaks in our saturated absorption signal. As the graphs show, increasing the neutral density value yields spectra with clearer peaks. We use the 20dB neutral density filter because it provides the necessary saturation intensity and gives us the best spectrum (this is not obvious because of the scaling).

4.8 Closing Remarks

In order to stabilize the frequency of our laser, we need a very precise and stable reference frequency. The hyperfine atomic transition frequencies of $^{85}\text{Rb}$ provide several such stable reference frequencies. By means of Doppler-free saturated absorption spectroscopy, we produce a spectrum of narrow peaks which correspond to these hyperfine transitions. The central frequency at the very summit of one of these peaks is ideal for locking our laser frequency. We are able to tune our laser to any of these frequencies by means of adjusting the parameters described in Chapter 3, particularly the laser current and grating angle which allow for fine tuning. Chapter 5 describes how we can stabilize the frequency of our laser to a hyperfine atomic transition frequency by using the signal from our lock-in amplifier to correct the laser frequency whenever it drifts from the reference frequency.
Chapter 5

Stabilizing the Frequency of Our Laser

5.1 Introduction

The key to stabilizing the frequency of our laser is using a negative feedback signal, produced by our lock-in amplifier, that continuously forces the laser back onto the peak of a hyperfine atomic transition as the laser frequency naturally drifts in one direction or the other, away from the peak.

In locking the frequency of our laser to a hyperfine atomic transition frequency in $^{85}$Rb, the only tuning parameter that we manipulate is the grating angle. The error signal, fed to the PZT, continuously changes the grating angle so the laser frequency stays locked onto the point where there is no $\omega_d$ signal as measured by the lock-in amplifier. This will keep our laser stable at a hyperfine atomic transition of $^{85}$Rb.

5.2 Dither and Input Signals

A dither signal (2V, $\omega_d = 512$Hz) is provided to our lock-in amplifier by an external sine wave generator. After being attenuated by -40dB, this dither signal (now 0.2mV) also goes to the PZT driver. The dither signal causes the PZT to expand and contract, dithering the grating angle and therefore the laser frequency. The dithered laser light is sent through the cell. Our experiment responds at the same frequency $\omega_d$, providing the input signal for our lock-in amplifier. The input signal is the Doppler-free saturated absorption signal as described in Chapter 4.
5.3 The Error Signal

When our lock-in amplifier is provided with both the input signal (Eq. 5.1) and the dither signal (Eq. 5.2), it generates a DC error signal that is proportional to the amplitude of \( 1\omega_d \) signal present in the input signal, \( A \). The mixer in our lock-in amplifier multiplies the dither and input signals together to produce a mixed signal (Eq. 5.3) with the sum and difference frequency components. Assuming that these signals have been made in phase by the phase shifters of our lock-in amplifier, the output of the mixer is given by Eq. 5.3.

\[
V_{\text{in}} = A \sin(\omega t) \quad \text{[Eq. 5.1]}
\]

\[
V_d = B \sin(\omega_d t) \quad \text{[Eq. 5.2]}
\]

\[
V_{\text{mixed}} = \frac{AB}{2} \left[ \cos(\omega t - \omega_d t) - \cos(\omega t + \omega_d t) \right] \quad \text{[Eq. 5.3]}
\]

As displayed in Fig. 5.1, when the laser frequency is on resonance with the atomic transition frequency, one dither cycle passes twice over the absorption peak, producing a \( 2\omega_d \) absorption signal. This signal is detected by the photodiodes and is fed into the input channel of our lock-in amplifier. In this case \( \omega = 2\omega_d \). So, Eq. 5.1 becomes

\[
V_{\text{in}} = A \sin(2\omega_d t) \quad \text{[Eq. 5.4]}
\]

This input signal is multiplied with the dither signal (Eq. 5.2). The resulting mixed signal contains a \( 1\omega_d \) difference frequency component and a \( 3\omega_d \) sum frequency component,

\[
V_{\text{mixed}} = \frac{AB}{2} \left[ \cos(1\omega_d t) - \cos(3\omega_d t) \right] \quad \text{[Eq. 5.5]}
\]

The amplitudes of both of these frequency components are reduced by the low-pass filter in our lock-in amplifier. Hence, no DC error signal is produced when the laser frequency is on resonance with the atomic transition frequency, as desired.
On the other hand, when the laser frequency is not on resonance with the atomic transition frequency, one dither cycle produces a $1\omega_d$ absorption signal. In this case, the input becomes a $1\omega_d$ signal (i.e. $\omega = \omega_d$) as displayed in Fig. 5.1, and so,

$$V_{in} = A\sin(\omega_d t)$$  \hspace{1cm} \text{[Eq. 5.6]}

This input signal is multiplied with the dither signal (Eq. 5.2). The resulting mixed signal contains a $0\omega_d$ (i.e. DC) difference frequency component and a $2\omega_d$ sum frequency component,

$$V_{mixed} = \frac{AB}{2} \left[ \cos(0\omega_d t) - \cos(2\omega_d t) \right] = \frac{AB}{2} \left[ 1 - \cos(2\omega_d t) \right]$$  \hspace{1cm} \text{[Eq. 5.7]}

The $2\omega_d$ sum component is eliminated by means of the low-pass filter, leaving only the DC voltage, which is the error signal. Hence, an error signal is produced whenever the laser frequency is not on resonance with the atomic transition frequency. As displayed in Fig. 5.2, the magnitude and sign of this error signal depend on how far off and in what direction the laser frequency is with respect to the atomic reference frequency.
Fig. 5.1: This is a theoretical atomic absorption spectrum. It is equivalent to the saturated absorption peaks in Fig. 4.6. A small dither at frequency, $\omega_d$, is applied to the laser frequency. The dither signal is modified by the experiment and then fed into the input channel of our lock-in amplifier which measures the amplitude of the $1\omega_d$ component of the input signal. At different laser frequencies, the amplitude of the $1\omega_d$ signal varies. However, when the laser is on resonance with the atomic reference frequency, the amplitude of the $1\omega_d$ signal is zero.

As displayed in Fig. 5.2, any time the laser frequency drifts away from the atomic reference frequency, an error signal develops which is proportional to the amount of frequency drift. This error signal can be used to force the laser frequency back to the atomic reference frequency. Whenever the laser frequency is lower than the atomic transition frequency, a positive error signal is produced to raise the laser frequency. On the other hand, whenever the laser frequency is higher than the atomic transition frequency, a negative error signal is produced to lower the laser frequency. When the laser frequency is on resonance with the atomic reference frequency, there is no error signal.
Fig. 5.2: This theoretical error signal (derived from the absorption signal in Fig. 5.1) indicates the amount of $1\omega_d$ signal at various laser frequencies. The zero-crossing point of the error signal corresponds to the summit of the absorption peak. That is, when the laser frequency is on resonance with the $^{85}\text{Rb}$ atomic transition, no error signal is produced. Conversely, when the laser frequency is not on resonance, an error signal is produced. To the left of the zero crossing, the error signal is positive and to the right it is negative. These correspond to the positive and negative slopes on either side of the absorption peak, respectively. The peaks of the error signal are the inflection points (i.e. maximum and minimum slopes) present in the absorption spectrum. Stabilizing is possible as long as the laser frequency is not allowed to drift further than these peaks.
Before attempting to lock our laser, we ensure that the lock-in amplifier is producing an error signal with the correct shape (see Fig. 5.3).

**Fig. 5.3:** This figure displays the two largest crossover peaks as well as the $F = 3$ to $F' = 3$ transition peak from the saturated absorption spectrum of $^{85}\text{Rb}$ along with their corresponding error signals which overlap. The error signals from our lock-in amplifier display the expected shape for each of the peaks. Hence, the output of our lock-in amplifier is suitable for laser frequency stabilization.

A negative feedback loop is created when a fraction of the error signal from our lock-in amplifier is provided to the PZT driver (see Fig. 5.4). If the frequency of the laser drifts to one side of the peak, the error signal becomes non-zero. This cases the PZT to contract or expand (depending on which side of the peak the laser has drifted to), changing the grating angle and, therefore, the frequency of the laser. The PZT continues to change the grating angle until there is no error signal. The negative feedback loop forces the laser frequency back on top of the transition peak where the laser is on resonance with the atomic reference frequency.
Fig. 5.4: This is the negative feedback loop that we use to lock our laser. In order to get additional low frequency feedback, we feed back a fraction of the error signal both directly to the PZT driver and through a low-pass filter. The dither signal is attenuated by 60dB. The error signal fed to the PZT driver is attenuated by 30dB, while the error signal which passes through the low-pass filter is only attenuated by 20dB.

5.4 Stabilizing the Frequency of our Laser

Since the first crossover peak is the largest in the saturated absorption spectrum (see Figs. 4.6 and 5.3) of $^{85}$Rb, we choose this peak to lock the frequency of our laser to. By manipulating the laser tuning parameters discussed in Chapter 3, we center the frequency of the laser on the very summit of this peak. Without feedback, the laser frequency drifts over time as indicated by the large error signal in Fig. 5.5. The production of a nonzero error signal by our lock-in amplifier reveals that the laser frequency is not on resonance with the atomic transition. The “unlocked” data in Fig. 5.5 demonstrates the instability of the frequency of a free-running laser. The purpose of this thesis is to eliminate this drift.
When the feedback loop is enabled, however, we see that the error signal is nearly zero, meaning that the laser frequency is locked on the atomic transition. Without feedback, the laser frequency drifts away from the transition peak in less than 1 minute, producing a large error signal. On the other hand, with feedback, the laser frequency stays locked on the atomic transition for 40 minutes, producing a very small error signal. The data shows that the error signal from our lock-in amplifier was able to maintain our laser stable at a specific frequency for a very reasonable amount of time.

Fig. 5.5: Without feedback from our lock-in amplifier, the frequency of our laser drifts away from the transition peak in less than 1 minute, producing a large error signal. However, when the feedback is enabled, our lock-in amplifier is able to lock the laser to the atomic transition of $^{85}$Rb as displayed by the nearly zero error signal. A jump in the laser frequency occurred around $t = 18\text{min}$, but the lock-in amplifier was able to regain the lock. The frequency of our laser became unstable shortly after the 40 minutes that it took to record this data.

Since the largest crossover peak that we locked to is 5MHz wide at half maximum (see Fig. 5.3) and we stay locked on top, our laser frequency is certainly stabilized to less than 5MHz. This represents a fractional frequency stability of better than $10^{-8}$ over the 40 minute period.
Conclusion

The locked data in Fig. 5.5 represents the achievement of our goal of stabilizing the frequency of our laser. We have reached this goal by building and assembling every part of the system ourselves, from the lock-in amplifier to the laser system, and saturated absorption spectroscopy setup. After a lot of time and effort, we have also gained a valuable understanding about the operation and function of every component in our experiment.

The stability of the lock in Fig. 5.5 is affected by the total gain (product of AC and DC amplifier gains) of the error signal from our lock-in amplifier, the fraction of the error signal fed back to the laser via attenuators, and the time constant of the low-pass filter in our lock-in amplifier. Adjusting all of these variables to obtain a stable lock requires time and patience. We have been able to show that our lock-in amplifier is able to produce an error signal that can keep our laser stabilized for a reasonable length of time. We believe that under the right settings, the laser frequency can remain locked on the atomic transition for a much longer time.

Having stabilized the frequency of our laser, it is possible to run experiments which require a highly stable frequency, such as laser cooling of Rubidium atoms. This technique slows Rubidium atoms down to extraordinarily low temperatures, allowing one to better observe and understand the behavior of these atoms and their interactions with each other. The locking technique discussed in this thesis will also be used to stabilize lasers for excitation of Lithium atoms in Professor Oxley’s atomic beam experiments.
